Highly mismatched alloys have been predicted to exhibit enhanced thermoelectric properties. Here we report on transport properties of one such system, nitrogen-doped ZnTe epitaxial layers on GaAs (100). Hall effect, electrical resistivity, and Seebeck coefficient measurements were performed between 5 K and 300 K for samples with a room temperature hole concentration of 0.34–2.16 × 1019 cm−3. Significant phonon-drag thermopower reaching 1.5–2.5 mV K−1 was observed. Fermi-Dirac statistics was used to analyze the transport parameters of ZnTe:N films assuming a single parabolic band. The power factor demonstrates a measurable improvement with increasing nitrogen concentration.

ZnTe is a direct wide band gap [2.27 eV at 300 K (Ref. 1)] II-VI semiconductor with zincblende crystal structure, utilized in optoelectronic applications including green light emitting diodes2 and solar cells.3 Recently, highly mismatched alloys (HMAs) of II-VI compounds, formed by alloying isovalent constituents with vastly different electronegativities (e.g., ZnSe1−xOx), have been proposed as candidates for promising thermoelectric performance.4 The optimistic prediction is based on an assumption that such materials would possess an enhanced power factor defined as

\[ PF = \frac{S^2 \sigma}{\rho} \]

where \( S \) is the Seebeck coefficient or thermopower and \( \sigma \) is the electrical conductivity. Practically, however, co-doping of additional species is required in order for such isoelectronic HMAs to function with the desired carrier concentration. An alternative approach of forming nonisoelectronic HMAs may provide a solution. Historically, nitrogen has proven to be a controllable p-type dopant in ZnTe (Refs. 5–7) with hole concentrations of up to 1020 cm−3. Nevertheless, systematic studies of the thermoelectric properties of such nitrogen doped p-type ZnTe (ZnTe:N) thin films remain largely unknown in the literature. In this letter, a series of ZnTe:N epitaxial layers with varying N content is studied to examine their temperature dependent thermoelectric properties.

ZnTe:N materials were grown on semi-insulating GaAs (100) substrate by molecular beam epitaxy (MBE) using solid source effusion cells for Zn and Te and an electron cyclotron resonance plasma source for nitrogen incorporation. Thickness of the ZnTe:N films (1–2 μm) was determined by analyzing optical reflectance spectral data, whose details were described elsewhere.8 Photoluminescence (PL) spectra of the ZnTe:N films were collected at 20 K using excitation from a He-Cd 325 nm laser, a grating spectrometer, lock-in amplification, and a photodiode detector. Rectangular-shaped samples for Hall-effect measurements (2 mm × 6 mm) and Seebeck coefficient (3 mm × 10 mm) characterization were cut out of the as-grown sample (10 mm × 10 mm) by a diamond saw, with the sample glued on an aluminum block using crystal bond. The residual glue was carefully removed using acetone and then flushed by methanol for 3 min. Tiny indium contacts were soldered on to the sample. Silver epoxy contacts were also used on selected fresh samples in order to double check transport results, which confirmed that none of the phenomena reported in this letter are artifacts possibly induced by indium contacts becoming superconducting at low temperatures. Hall coefficient \( R_H \) and electrical resistivity \( \rho \) measurements were performed on the same sample from 5 K to 300 K in a Quantum Design Magnetic Property Measurement System (MPMS), equipped with a 5.5 T superconducting magnet, using a Linear Research ac bridge with 16 Hz excitation. Results from warming and cooling cycles were identical. Hall data were taken for both positive and negative magnetic fields to eliminate effects due to probe misalignment. The Hall resistance is linear in terms of the applied magnetic field. The concentration of holes and their Hall mobility were then estimated from the Hall coefficient and the electrical resistivity. For comparison, the amount of incorporated nitrogen atoms in selected samples was characterized using secondary ion mass spectrometry (SIMS). The Seebeck coefficient \( S \) and the electrical resistivity \( \rho \) were measured from 2 K to 300 K in a home-made cryostat equipped with a radiation shield, using a longitudinal steady-state technique.9,10 The base temperature of the sample holder is controlled via a Lakeshore 340 temperature controller. For measurements of the Seebeck coefficient \( S = \Delta V/\Delta T \), one end of the sample was clamped to a copper heat sink, and the other end was provided with a current-driven strain gauge heater as the heat source. Temperature gradients along the length of the sample were monitored using Chromel-Gold/Iron (0.07 at. %) thermocouples soldered onto the samples with tiny indium contacts. Fine copper wires (25 μm in diameter) were used as voltage probes. Typical temperature difference between the hot and cold ends of the sample is 0.3 K above the liquid nitrogen temperature and around 0.1 K at the liquid helium temperature range. Different heater power was supplied at various temperatures yielding consistent Seebeck coefficient readings. The measured Seebeck coefficient \( S \) was corrected for the contribution from the Cu wires.11 For measurements of the electrical
incorporation (from samples 1–5) improves the overall electrical conductivity due to higher carrier concentration and also exhibits a surprising qualitative change in the temperature dependence of electrical resistivity. At the highest doping levels (samples 4 and 5, $p > 1.5 \times 10^{19} \text{cm}^{-3}$), the electrical resistivity has a positive temperature coefficient over most of the temperature range, i.e., electrical resistivity increases as temperature increases. This is a typical behavior of the heavily doped degenerate semiconductor. Note that acceptor formation via nitrogen incorporation in ZnTe is typically attributed to the substitution of N on the lattice sites of Te, resulting in an acceptor activation energy of 46 meV.12

At such high doping levels, acceptor states originated from nitrogen impurity likely form an impurity band, as implied by the nearly temperature independent hole concentration in Fig. 1(a). As the nitrogen incorporation is gradually reduced from this highly doped regime (samples 3, 2, and 1), the electrical resistivity profile deviates from a simple metallic behavior, with a peak observed in the temperature range between 50 K and 100 K. This could be related to the more subtle details of the nitrogen induced impurity level/band in ZnTe, which requires further investigation. To shed more light on the effect of N-doping, PL spectra of various ZnTe:N samples, together with a pure ZnTe sample as

TABLE I. Typical transport coefficients of various ZnTe:N thin films at 300 K, including nitrogen concentration [N] from SIMS measurement, Hall coefficient $R_H$, hole concentration $p$, electrical resistivity $\rho$, Seebeck coefficient $S$, thermoelectric power factor $PF$, Hall mobility $\mu_H$, and effective mass $m^*$.
reference, were collected at 20 K. They reveal a red shift of the band edge peak upon N-doping, as shown in Fig. 3. This effect may correspond to the formation and broadening of the nitrogen induced impurity band, as more nitrogen atoms are incorporated into the system.

Figure 2(b) shows a plot of the temperature dependent Seebeck coefficient $S$ of the ZnTe:N films. $S$ is positive for all samples suggesting $p$-type conduction, in agreement with the Hall effect measurements. The Seebeck coefficient at 300 K decreases as the concentration of holes increases, which agrees with the typical behavior of a degenerate semiconductor. At the lowest temperatures, $S$ increases rapidly to a maximum at $\sim 13$ K and then decreases until $\sim 100$ K.

The greatly enhanced Seebeck coefficient at low temperatures (as high as 1.5–2.5 mV K$^{-1}$) is a manifestation of strong electron-phonon interaction otherwise known as the phonon-drag effect. The peak position of the phonon-drag Seebeck coefficient ($\sim 13$ K) in ZnTe:N coincides with the peak position of the phonon thermal conductivity in bulk crystals of ZnTe. This is in accord with the concept of the phonon-drag effect. In the presence of a thermal gradient, non-equilibrium phonons impart their momentum to electrons, resulting in a momentary electric current just as an applied electric field would do. However, under an open circuit condition (the condition under which the Seebeck coefficient is measured), an electric field is set up which counters such impulsively generated flow of electrons. By the phonon-drag Seebeck coefficient, one understands the ratio of this induced electric field to the applied thermal gradient. Unlike the diffusion component of the Seebeck coefficient that is present at all temperatures, the phonon-drag contribution is manifested only at temperatures where phonon-electron processes dominate over all other modes of phonon scattering. Practically, this implies low enough temperatures where phonon-phonon Umklapp processes are infrequent, but temperatures not so low that the population of phonons would be very small. Since these same phonons are responsible for heat conduction, the positions of the phonon-drag peak and the peak in the lattice thermal conductivity essentially coincide. It is worthwhile to note that the thermal conductivity of GaAs substrate peaks at a similar temperature of $\sim 10$ K. Thus, any phonons leaking from the substrate into the film might, in principle, also contribute to phonon drag in ZnTe:N grown on GaAs. However, as pointed by Wang et al., such leaking phonons to make an appreciable contribution to the phonon drag, the film must be very thin (a few tens of nm), and having a near perfect lattice match with the substrate, a situation is difficult to realize in II-VI compounds.

While examples of significant phonon-drag Seebeck effect are often seen in both metals and semiconductors, it is exceptionally rare to see any signature of phonons dragging charge carriers in the electrical resistivity. The reason why phonon-drag effects are easily detected in the Seebeck coefficient and not in the electrical resistivity lies in the fact that the phonon-drag Seebeck effect is a first-order effect in the interaction between non-equilibrium phonons and electrons while it is a second-order effect as far as the electrical resistivity is concerned. Electrons, accelerated by the applied electric field, lose some of their momentum by being scattered by phonons and thus causing a flow of phonons which then acts back on the electrons. We would like to point out that in Fig. 2(c), at the lowest temperatures $\sim 13$ K, there is a local plateau in the electrical resistivity profile which coincides with the position of the phonon-drag Seebeck effect peak. Upon cooling down, instead of decreasing monotonically, the electrical resistivity tends to (quasi-) saturate in the regime where significant phonon-drag Seebeck effect is

**FIG. 2.** Temperature dependent (a) electrical resistivity $\rho$ and (b) Seebeck coefficient $S$ of ZnTe:N MBE thin films with various doping levels. (c) A correlation between the Seebeck coefficient peak ($\sim 13$ K) and an electrical resistivity plateau in sample 2, suggesting that phonon drag leaves an imprint on the temperature profile of the electrical resistivity.

![Figure 3](image.png)

manifested. This result actually might be one of very rare examples where phonon drag exerts an influence in the electrical resistivity. Further experimental and theoretical work is needed to ascertain this point.

At $T > 150$ K, $S$ increases linearly with $T$, as shown in Fig. 4(a), due to carrier diffusion driven by the temperature gradient. For a $p$-type degenerate semiconductor, $S$ can be expressed as follows: 

$$S = \frac{k_B}{e} \left[ r + \frac{5}{2} F_{r+3/2} (\eta) - \eta \right], \quad (1)$$

where $k_B$ is the Boltzmann constant, $e$ the elementary charge, $r$ the index of energy dependent relaxation time $\tau = \tau_0 e^{-\frac{h \omega}{k_B T}}$ (taken to be $-1/2$ for acoustic phonon scattering), $\eta = E_F/k_B T$ the reduced Fermi level measured from the top the valence band, and $F_j(\eta)$ the $j$-th Fermi integral given by

$$F_j(\eta) = \int_0^\infty \exp\left( \frac{\xi}{\eta} - 1 \right) d\xi. \quad (2)$$

The observed effective mass $(1.3–1.7 m_0)$ at $300$ K is significantly larger than the effective mass for intrinsic ZnTe $(m^*_0 = 0.2 m_0)$. This observation is consistent with a modified band structure due to the formation of an impurity band via heavy nitrogen doping. The Pisarenko plot of the Seebeck coefficient versus hole concentration at $300$ K is illustrated in the Fig. 4(c), where dashed lines are analytical results from Eqs. (1) and (3) with the effective mass as a fitting parameter. It verifies the validity of the single parabolic band model for the N-doped ZnTe:N system. In addition, with the N-doping level increased, the power factor (PF) improves to $503 \mu W m^{-1} K^{-2}$ (see Table I) for the highest doping level explored in this study.

We have performed low temperature thermoelectric characterization on a series of nitrogen doped ZnTe thin films grown by MBE. We have observed a significant phonon-drag peak in the Seebeck coefficient at $\sim 13$ K in all ZnTe:N samples corresponding to a few mV K$^{-1}$. Upon tuning the N-doping level, qualitative changes in the temperature dependent electrical resistivity profile develop, leading to a marginal improvement of the power factor at the highest doping level. A single parabolic band model proves to be a valid description for the ZnTe:N system at the doping levels we have explored.
